Total Vegetation Control for Industrial Sites Second Year Results
Combinations of Diuron, Flumioxazin, Glyphosate, and Sulfentrazone for Total Vegetation Control
Evaluation of Westar® and Krovar® to Control Marestail (Conyza canadensis (L.) Cronq.) in Bareground Situations
Purple Loosestrife (Lythrum salicaria L) Identification and Control
Chemical Control of Chinese Silvergrass (Miscanthus sinensis Anderss.) 19
Identification and Control of Common Reed (<i>Phragmites australis</i> (CAV.) Trin. ex Steud.)
Evaluation of Imazapyr, Glyphosate, and Triclopyr for Japanese Knotweed (<i>Polygonum cuspidatum</i> Sieb. & Zucc.) Control
Identification and Control of Serecia Lespedeza (<i>Lespedeza cuneata</i> (Dum. – Cours.))
Dormant Stem Herbicide Applications for Bush Honeysuckle Control 33

Table of Contents

Forward

The information provided in this document represents a collaborative effort between the Roadside Environment Branch of the Kentucky Transportation Cabinet and the Department of Plant and Soil Sciences in the College of Agriculture at the University of Kentucky. The main priority of this project was to collect and disseminate information to the KTC REB to increase the efficiency of operations aimed at roadside environment management.

This report contains a summary of research conducted during 2005. This document is primarily for the use of the Kentucky Transportation Cabinet. Other use is allowable given proper credit to the authors.

Weather data was obtained from weather recorders located on site of the Princeton Agricultural Research Station in Princeton, KY (located in western Kentucky), the Spindletop Agricultural Research Station in Lexington, KY (located in central Kentucky), and a University of Kentucky operated weather station located in Jackson, KY (located in eastern Kentucky)

Any questions, concerns, complaints, or praise regarding this publication should be directed to:

Mitch Blair Vegetation Management Research Specialist

Acknowledgements

The Kentucky Transportation Cabinet funded the research conducted during the 2005 season. A special recognition must go to P. David Cornett, Mike Smith, and others at the Central Office in Frankfort for having the foresight and perseverance to see this project to fruition. Special acknowledgement must also go to the twelve district roadside environment managers and their crews for contribution of ideas and land to conduct part of this research.

This work was accomplished with the help of Garrick Howell, a student at UK, who aided in study initiation, data collection and mining, and plot maintenance. Personnel in the Weed Science group who also aided in this project in terms of labor, equipment, and ideas include Charlie Slack, Ted Hicks, Jack Zeleznik, Joey Buckles, Dr. J.D. Green, and Dr. Jim Martin. Appreciation is also given to the farm crews at Spindletop Research Station for equipment and plot maintenance.

Appreciation is extended to Brett Wilson and Hopkins County Coal along with Paul Merrick and South Kentucky RECC for providing land area to perform serecia lespedeza and brush research, respectively.

The research could not have been accomplished if not for the generous contributions of product. Contributors of product used include:

Allegare, LLC BASF Corporation CWC Chemical, Inc Dow AgroSciences DuPont PBI Gordon Riverdale / NuFarm Inc Townsend Chemical

External funding for research projects was also received from BASF Corporation, Dow AgroSciences, LLC, and DuPont. The financial support of these organizations is greatly appreciated.

We sincerely appreciate the effort and continued support of all our cooperators and look forward to future endeavors.

Species List

The following is a list of plant species discussed in the following document.

Scientific Name	Common Name
Ambrosia artemisiifolia L.	Common ragweed
Ambrosia trifida L.	Giant ragweed
Carduus nutans L.	Musk thistle
Conyza canadensis (L.) Cronq.	Marestail
Festuca arundinacea Schreb.	Tall fescue
Lespedeza cuneata Dumont	Serecia lespedeza
Lespedeza procumbens Michaux.	Decumbent lespedeza
Lonicera maackii (Rupr.) Herder	Amur honeysuckle
Lonicera morrowii Gray	Morrow's honeysuckle
Lonicera tatarica L.	Tatarian honeysuckle
Lythrum salicaria L.	Purple loosestrife
Micanthus sinensis Anderss.	Chinese silvergrass
Phragmites australis (CAV.) Trin. Ex Steud.	Common reed
<i>Plantago lanceolate</i> L.	Buckhorn plantain
Polygonum cuspidatum Sieb. & Zucc.	Japanese knotweed
Setaria glauca (L.) Beauv.	Yellow foxtail
Trifolium pretense L.	Red clover
Trifolium repens L.	White clover

Total Vegetation Control for Industrial Sites Second Year Results

Introduction

Total vegetation control is required for several types of industrial sites, including power substations, roadside vegetative free zones, storage lots, pipeline facilities, etc. Maintenance and safety issues are prevalent in these sites as the presence of vegetation can have several detrimental effects. Power substations and pipeline yards need to be vegetative free to remove fire fuel load and decrease the possibility of vegetation causing equipment failure and increased maintenance costs. Highway roadsides need to have a vegetative free zone underneath guardrails and in vehicle recovery zones for several reasons. Vegetation existing at pavements edge can block drainage resulting in standing water. These areas will also pose safety and maintenance concerns if vegetated due to fire concerns from accidents and littering of ignited material (i.e. cigarettes) and the effects vegetation will have in increasing the amount of cracks in the pavement and increasing freeze – thaw potential.

Applications of broad spectrum residual herbicides have become the mainstay for bareground maintenance operations. Preemergent type herbicides work by inhibiting the germination of seeds present in the soil / strata or being translocated via the roots and/or seed shoots. Examples of these types of herbicides are those containing prodiamine, pendimethalin, bromacil, and diuron. If actively growing weeds are present, it is necessary to combine the preemergent compound with a postemergent herbicide such as glyphosate or imazapyr. Many compounds offer both pre and post emergent activity. Examples of these include flumioxazin, diuron, and sulfumeturon. There is a balance in choosing the most effective compounds to create the desired results while minimizing off target damage and cost per acre.

A study was initiated in April of 2004 to examine the ability of several 'bareground' products and combinations with other herbicides for duration of control. The entire study was reapplied on the same plots in April of 2005 to determine the effect of sequential applications on duration of total vegetation control and effectiveness of site reclamation.

Methods and Materials

The study was initiated in April of 2005 to compare flumioxazin, pendimethalin, and diuron as bareground products for length of control. The study site was a retired storage area along Interstate 75 in central Kentucky. The study site had areas completely covered with herbaceous vegetation while other areas still completely void of vegetation from the previous years application. The substrate was a compacted gravel base with little to no soil present with essentially no slope differences within and between the study blocks. Twenty seven chemical treatments and one untreated control were screened in a completely randomized block design with three replications (Table 1).

	° °	Active Ingradiant(g)

Table 1: Treatment list for bareground trial (Note: Prices based on 2004 estimates)

Predominant vegetation at the second year initiation included decumbent lespedeza, white and red clover, and tall fescue. Plots were $3.3' \times 20'$ with 5' running checks in between plots. Applications were made on April 20^{th} , 2004 using a CO₂ powered sprayer equipped with 2 TeeJet 8008 SS flat fan nozzles at 50 GPA. All treatments included a nonionic surfactant at 0.25 % v/v. Costs per acre are approximate and are for comparison purposes only.

Data collected in the first trial included pre-application measurement of cover by species, percent cover of dead vegetation, and percent cover bareground. Follow up measurements were taken at approximately two week intervals after treatment. Data were analyzed using analysis of covariance (pre-application data as the covariate) in SAS software and adjusted treatment means were compared at each time interval using Tukey's Honest Significant Difference (HSD) method at p = 0.05.

The second application was performed on April 15th, 2005 with the same methodology as the first trial. Data collected was performed on a less intense schedule than the first trial and was collected at 3, 10, 15, and 21 WAT (weeks after treatment). Data analysis was performed with the same methodology as the first year's data set.

Results and Discussion

Results discussed here will focus on the results of the 2005 application as compared to the 2004 application. Complete results from the 2004 application discussing site reclamation with one application can be found in <u>Noncrop and Industrial Vegetation</u> <u>Management Weed Science 2004 Annual Research Report (Information Note 2005 NCVM-1)</u>. Results presented here will statistically compare treatment means with the 2005 year and discuss differences and similarities with the 2004 trial.

Second Year Results

All treatments, including the untreated, had relatively high levels of percent bareground (> 65%) at 3WAT (Table 2). The levels of bareground achieved at this time interval is higher than that at a similar time period in the first year (Table 3). This shows the effectiveness of these treatments to provide increased levels of control at early stages of evaluation after sequential applications.

There were no statistically significant differences in any of the Payload / Arsenal tank mixes at any evaluation interval during the second year trial (Table 2). The highest levels of control generally occurred at 10 WAT, with the exception of Payload @ 10 oz + Arsenal @ 16 fl oz, which occurred at 3 WAT, and Payload @ 10 oz + Arsenal @ 32 fl oz, which occurred at 15 WAT; however, these differences should not be considered operationally significant. A trend does exist that shows increased levels of control with the high rate of Arsenal (32 fl oz) regardless of the rate of Payload. Second year results generally showed operationally higher levels of control at the end of the trial as compared to the end of the first year trial (Figure 1). This can be attributed to the effect of the 2004 application in reducing weed pressure and difference in precipitation amounts between the two years as rainfall levels in 2004 were above normal while rainfall levels in 2005 were below normal.

Two rates of Payload alone, 8 and 10 oz, had effective levels of control (> 85 %) at 3 WAT (Table 2). Similar to the first year results, these control levels began to decrease between the 3 and 10 WAT evaluations and continued to decline throughout the trial. The Payload / Oust tank mixes produced similar results in the second year as in the first year. Levels of control were far superior to that of the Payload alone treatments through the entire second year. Levels of control with the Payload / Oust tank mixes were relatively higher at the end of the second year as compared to the end of the first

year (Figure 2). Payload / RoundUp tank mixes provided effective levels of control at 3 WAT in the second year (> 90 %); however, declined to unacceptable levels at the end of the second year (Figure 2). Results with the Payload / RoundUp tank mixes at the end of the second growing season were similar to those at the end of the first growing season (Figure 2).

Pendulum Aquacap treatments showed acceptable levels of control at 3WAT; however, control levels began to decrease between the 3 and 10 WAT evaluations. The high rate of Pendulum Aquacap (128 fl oz) tank mixed with RoundUp at 64 fl oz showed acceptable levels of percent bareground (> 90 %) at 15 WAT yet these control levels dropped sharply (69 %) at 21 WAT (Table 2). Results of the Pendulum Aquacap treatments at the end of the second year were consistent with the results of the same treatments at the end of the first year (Figure 3).

Sahara treatments performed very well and had control levels greater than 90% for all treatments through 15 WAT (Table 2). These treatments maintained somewhat acceptable levels of control (> 85 %) through 21 WAT. There were no significant differences between any of the Sahara treatments during the entire second year. Results at the end of the second growing season were comparable to those at the end of the first growing season (Figure 3).

Combinations of Diuron, Flumioxazin, Glyphosate, and Sulfentrazone for Total Vegetation Control

Introduction

Industrial vegetation managers often require that certain areas remain free of vegetation. Areas may include roadside shoulders and guardrails, power substations, and pipeline yards. The reasons for vegetation free areas range from safety concerns to maintenance issues. Herbicides traditionally used for these types of applications are typically preemergent type herbicides; with little to no post activity; however some may have effective amounts of post activity. There are concerns that the products used, such as sulfumeturon or diuron, may cause off target damage through lateral movement or desirable species uptake. These herbicides are usually applied at high per acre rates as well. Existing chemistries, such as imazapic, can be applied at lower per acre rates. Imazapic, an ALS inhibitor herbicide, has soil residual activity, little to no movement in the soil, and little to no activity on woody plants, all of which are desirable characteristics for a 'bareground' herbicide. A study was initiated in May of 2005 to evaluate Journey, a formulated blend of imazapic and glyphosate, for its ability to provide broad spectrum control of vegetation in bareground situations.

Methods and Materials

The study was installed on May 10, 2005 at the retired KTC storage lot at Ironworks Pike and I – 75 in Lexington, KY. Eleven chemical treatments and one untreated check were replicated three times in 5' X 20' plots arranged in a randomized complete block design (Table 1). Predominant vegetation included buckhorn plantain, white clover, common ragweed, and tall fescue. Treatments were applied using a handheld CO₂ sprayer at 20 GPA and included a nonionic surfactant at 0.25 % v/v. All plots were treated with 1.25 % v/v solution (equivalent to 32 fl oz / ac) of RoundUp Pro one hour after application to provide burndown of initial weed pressure. Plots were evaluated before application to obtain percent cover by species and percent bareground. Plots were then evaluated at 60, 90, and 120 DAT for the same information. Data was analyzed using analysis of covariance, with preapplication values as the covariate, due to the presence of a statistical difference in percent bareground values at initiation. Treatment means were compared using Tukey-Kramer's Test at p = 0.05.

Results

The Payload alone treatment and the Authority alone treatment were not as operationally and statistically effective as those that included Journey, Oust, and Karmex (Table 2). These two treatments never reached bareground levels greater than 85 % and dropped to unacceptable control levels at the end of the trial (120 DAT). All other herbicide treatments maintained high levels of control (> 90 %) at the end of the trial. This indicates the benefit of adding imazapic to Payload or Authority to obtain operationally successful control levels. Although there were no statistically significant differences between the Authority alone, Payload alone, and Journey + Authority

treatments at 120 DAT, the Authority alone and Payload alone treatments were significantly lower than all other herbicide treatments at 120 DAT.

The Karmex alone and Oust alone treatments were the only stand alone tested that produce excellent control levels through the entire study. The addition of Journey to Karmex did allow for the high levels of control to be consistently maintained through the trial; however, the two treatments were not statistically different at any time. Journey tank mixes with Karmex and Payload resulted in excellent control levels (> 95 %) at 120 DAT.

Figure 1: Treatment Mean Comparisons of Percent Bareground

Evaluation of Westar[®] and Krovar[®] to Control Marestail (*Conyza* canadensis (L.) Cronq.) in Bareground Situations

Introduction

Several herbaceous species can be problematic for vegetation managers involved in total vegetation management. Marestail, sometimes referred to as horseweed, can be problematic due to several of its physiological characteristics. Considered a winter or summer annual, germination characteristics of marestail can allow it to have the growth habit of a biennial. Germination of marestail seed can occur from fall through late summer. Seeds germinating in late summer may not be controlled by residual herbicide applications applied in the early spring if the available amount of active ingredient of herbicide has dissipated over the growing season. Seeds that germinate in late summer will overwinter in the rosette form and bolt early the following growing season and require a post application of herbicide to control.

Resistance of marestail to some herbicides can also lead to decreased control. Unfortunately, resistance to a specific mode of action is difficult to confirm. Glyphosate resistant biotypes are believed to occur in western and central Kentucky in production agriculture situations. It is also suspected that marestail may be developing resistance to ALS herbicides and certain biotypes are developing 'multiple resistance' to both glyphosate and ALS herbicides. The lack of control due to the germination characteristics described above may lead to a vegetation manager to assume resistance; however, this may not necessarily be the case.

In terms of total vegetation control scenarios, managers need to find treatments that include multiple modes of action, provide long lasting residual control to allow for one application per growing season, and consider rotating chemistries every few years to further prevent the development of resistance of marestail to glyphosate and ALS herbicides. A trial was initiated in May of 2005 to evaluate Westar (a.i. hexazinone and sulfometuron) and Krovar (a.i. bromacil and diuron) and their ability of provide total vegetation and marestail control.

Methods and Materials

The trial was located at the West Kentucky Research and Extension Center in Princeton, KY. The site had a history of traditional row crop research with appropriate soil characteristics. There is a suspicion that the area has ALS resistant biotypes of marestail present; however, this was never documented with laboratory tests. Dominant vegetation at initiation included marestail, yellow foxtail, and giant ragweed with marestail being the most dominant. The study was installed as a randomized complete block with three replications. Plots were 10' X 30', utilized a 2.5' running check between plots, and were treated with a CO₂ handheld sprayer at 20 GPA. All herbicide treatments included a nonionic surfactant at 0.25 % v/v. Eleven herbicide treatments and one untreated check (Table 1) were evaluated for total vegetation control and marestail control at 63 and 125 DAT. Control data was analyzed using ANOVA and treatment means were separated using Fisher's LSD at p = 0.05.

<u>Results</u>

The Payload alone treatment was significantly lower (63 %) than all other treatments tested for marestail control at 63 DAT (Table 1). Control values for this treatment increased at the 125 DAT interval and there were no significant differences across all treatments for marestail control at this evaluation interval. A rate effect was observed for the Westar alone treatments; as rate increased levels of bareground increased from 60 % to 95 % at 63 DAT. These control levels were not sustained; however, and control levels dropped below operationally acceptable levels for all Westar alone treatments at 125 DAT. The Krovar alone treatment provided satisfactory bareground levels at 63 DAT (92 %) and maintains effective levels of bareground through 125 DAT (90 %). The addition of Krovar to Westar did increase levels of bareground to operationally acceptable levels and above that of Krovar alone; however, there were no significant differences between any treatments that included Krovar at any evaluation interval. The Payload alone treatment never obtained operationally successful levels of total vegetation control and the Oust alone treatment, even though it provided satisfactory levels of bareground at 63 DAT (85 %), failed to maintain high levels of control at 125 DAT (43 %).

It is still unclear if the site was dominated by ALS resistant marestail. The site had been treated with FirstRate® (a.i. cloransulam methyl), an ALS herbicide, in the past and poor control levels were realized. Effective control levels were seen in this trial with Oust (a.i. sulfometuron), another type of ALS herbicide. This trial did show the effectiveness of another type of chemistry, the photosynthesis inhibitors bromacil and diuron (Krovar), to provide satisfactory levels of marestail control. This provides for an alternative chemistry for vegetation managers to prevent the establishment of marestail resistance while managing for total vegetation control.

Purple Loosestrife (Lythrum salicaria L) Identification and Control

Introduction

Purple loosestrife is a federally listed invasive perennial that typically occurs in wetland areas. This aggressive species has the potential to quickly replace native vegetation, degrade wildlife habitat, and obstruct drainage areas. Native to Europe, it is believed that purple loosestrife first arrived in North America through the ballast water of sailing ships. Occurrences have been reported in provinces of Canada and most of the continental United States (excluding Arizona, New Mexico, Louisiana, Florida, Georgia, and South Carolina) (USDA 2005). Purple loosestrife may possibly still be sold as an ornamental even though it is listed as a noxious weed in many states. Synonyms include purple lythrum and bouquet-violet (Uva et al 1997).

Identification

Purple loosestrife is an erect, multi-branched perennial that can obtain 1-2 meters in height. Juvenile plants tend to emerge from root buds or root crowns but may also develop from seed germination. Mature plants have square, sometimes six-sided, stems with leaves in opposite or whorled arrangement. Leaves are lanceolate to linear with entire margins and can be up to 10 cm in length. Root systems are thick and fleshy and develop a large woody crown as it matures (Uva et al 1997).

Flowers develop from July to September and are showy purple to lavender in long (10 - 40 cm) terminal spikes. Plants may produce up to 3,000 flowers which are insect pollinated (SE-EEPC 2006). Seeds are contained in capsules that are produced after pollination. Each capsule contains an average of 120 seeds and a plant may contain up to 900 capsules at one time (SE-EPPC 2006). A single plant has the potential to produce up to 2 million seeds in one year (Uva et al 1997). Seeds are wind dispersed but may also be transported via water and mud flow. Seeds can germinate over a wide range on temperature and environmental conditions (Young and Clements 2001), are long-lived, and can even remain viable up to 20 months in completely submerged conditions (SE-EPPC 2006).

Reproduction by seed germination is viable; however, sprouting from root buds or cuttings can dramatically increase the size of infestations. Mowing can displace stem fragments that can root to form new plants. Mowing can also create favorable conditions for increased stem density from existing root crown sprouts. Infestations will die back at the end of the season resulting in red foliage and dead stalks that persist throughout the winter.

The preferred habitat of purple loosestrife is wetland areas. It is considered an aquatic to semi-aquatic weed occurring in shallow water areas such as marshes, river banks, wet pastures, roadside ditches, and lake a reservoir shores. Plants grow best in moist soil conditions with full sunlight but can persist in areas with as much as 50 % shade (SE-EPPC 2006).

Control Options

<u>Mechanical Control</u>

Mechanical control methods, such as mowing and hand removal, are not deemed to be effective and may actually increase the size of a current infestation. Mowing will increase sprouting potential and may transport cuttings to areas currently uninfested to compound the problem. Hand removal may be appropriate in extremely small infestations; however, it is necessary to remove the entire plant, including the root system. Proper disposal of plant parts includes burning and transporting to an approved landfill. Transporting plant parts needs to be performed with care as this may lead to new infestations. Establishment of native vegetation in areas where infestations have been removed will reduce the potential of new seedlings through competition.

Biological Control

Biological control options for purple loosestrife have been researched extensively. *Galerucella calmariensis* L. and *Galerucella pusilla* Duftschmid are two types of leaf eating beetles that have been approved for biological control of purple loosestrife in the United States. Studies have shown that these two species of beetles are host specific to Lythrum species (Blossey et al 1994). The young larva feed on developing plant tissue while adult beetles will feed on almost any above-ground plant part. Native to Europe, these species where introduced in 1992 in a 5 - 15 year program to control purple loosestrife in the mid-Atlantic states and the program has since moved to the Midwest along with Colorado and Montana (Blossey et al 1994). Establishment of populations great enough to impact purple loosestrife may take up to 10 years; however, estimates are that once established North American populations of purple loosestrife will be reduced up to 90 % (Blossey et al 1994).

Hylobius transversovittatus Goeze, a nonnative root feeding weevil, has also been researched as a potential biological control agent for purple loosestrife (McAvoy et al 2004). Research is ongoing as to the impact this species will have in controlling purple loosestrife and its ability to establish great enough populations to justify its use.

Chemical Control

Chemical control of purple loosestrife can be achieved with the use of approved herbicides. Recommendations from non-profit and invasive plant management organizations (i.e. The Nature Conservancy, Southeast Exotic Plant Pest Council, etc) commonly include the use of an aquatic glyphosate as a foliar spray of 2 %. Glyphosate is a nonselective herbicide and may not leave desirable species in the treated area. The use of a selective herbicide, such as imazapyr or triclopyr, would be preferred to allow desirable grasses to survive herbicide applications and outcompete loosestrife regrowth.

Knezevic et al (2004) examined the ability for several selective herbicides along with glyphosate in their ability to control purple loosestrife for multiple years with one application along with the response of desirable vegetation. At 1 YAT, all treatments of

imazapyr, ranging from 20 to 96 fl oz of product, and metsulfuron, tested at 0.0125 and 0.25 oz of product, maintained greater than 90 % control of purple loosestrife. At 2 YAT, two rates of imazapyr, 64 and 96 fl oz, and the two rates of metsulfuron maintained 90 % control or greater. The imazapyr treatments did have a negative effect on desirable vegetation as the two high rates resulted in only 68 and 40 % vegetative cover, respectively. The metsulfuron treatments allowed for 100 % vegetative cover 2 YAT. Two rate of glyphosate tested, 64 and 96 fl oz, resulted in 70 to 75 % control, respectively, 2 YAT but allowed for 100 % vegetative cover. Triclopyr, tested at 1.5 and 2.5 qt, provided quick burndown at 10 WAT; however, the level of control decreased below 50 % over the next two years. The results of this study indicate that it is possible to eradicate purple loosestrife and, if used in with an integrated approach of replanting desirable species, one may be able to reclamate an infested site.

Research at the University of Kentucky

A trial was installed in central Kentucky to examine the ability for three herbicides, glyphosate, imazapyr, and triclopyr, all of which have an aquatic label, in controlling purple loosestrife. The study was located in the westbound cloverleaf in Interstate 64 at exit 35 near Shelbyville, KY. Purple loosestrife infestations were concentrated along and in a drainage way and due to area restrictions, only three treatments were installed in a randomized complete block design with three replications. The trial was installed on August 5th, 2005. Treatments were applied at 20 GPA and all treatments included NIS at 0.25% v/v. Treatments included imazapyr (formulated as Habitat®), triclopyr (Renovate 3®), and glyphosate (Aquamaster®). Plots were rated for percent control 6 WAT. This was the only evaluation made in the current growing season due to the time of year. Table 1 summarizes rates used and control levels by treatment.

There was no statistical difference across all treatments at the evaluation interval. 4 The triclopyr treatment did result in a higher level of control at 6 WAT (95 %) which may have operational implications. Triclopyr may be a desirable treatment if control levels are operationally acceptable since damage to desirable grasses would be minimal and may allow for the reduction of purple loosestrife regrowth through competition.

Chemical Control of Chinese Silvergrass (*Miscanthus sinensis* Anderss.)

Introduction

Chinese silvergrass, often times simply referred to as miscanthus, is a non-native bunchgrass that has become widespread in the eastern and southern parts of the United States. Occurrences are also being reported in Missouri, Illinois, Colorado, and California. Native to eastern Asia, this warm season grass species is used for bio-energy and paper pulp on Europe and Asia as well as erosion control and field hedges (Morisawa 1999). In the United States, *M. sinensis* is still widely sold as an ornamental with several varieties being imported and sold (Miller 2003).

The grass is a tall perennial that forms dense clumps. Leaves are upright, curly tipped with white midribs, approximately 2 centimeters wide, and can attain heights up to 1.5 - 2 meters. Plants flower in September through November and are pink to red at first turning brown to tan in the fall. Preferred habitats include sites with full sunlight and well drained soils. Reproduction by seed is not as common as sprouting from an extensive subterranean rhizomatous system. This characteristic allows Chinese silvergrass to form dense and extensive infestations along forest edges, roadsides, and other disturbed sites. Although not as aggressive as other invasive grasses, Chinese silvergrass is problematic in forest and roadside situations as leaves are extremely flammable and can be easily ignited.

Control options available appear to be limited. Mechanical control (mowing, burning, manual removal) does not appear to be effective as the entire root system will need to be removed to obtain complete control (Morisawa 1999). Mechanical control may also lead to the spread of the plant. Current chemical control recommendations are limited and include a foliar spray of a 2% glyphosate solution, a 1% imazapyr solution, or a combination of the two.

Chinese silvergrass has become established along Kentucky roadsides in the eastern regions of the state. These infestations are a concern due to line of sight issues, potential for fire, and mowing costs. A study was initiated in June 2005 to examine several herbicides available for grass control to evaluate their effectiveness on Chinese silvergrass.

Methods and Materials

The study was installed directly behind a guardrail on the eastbound lane of the Mountain Parkway in Wolfe County. Active ingredients tested included glyphosate, imazapyr, sulfosulfuron, clethodim, fluazifop + fenoxyprop, and imazapic (Table 1). Plots were 15' X 10' and arranged in a completely randomized block with 3 replications. Treatments were applied on June 21, 2005 at 20 GPA using a TeeJet® Boomless tip mounted on the rear of an ATV. Plots were evaluated for visual percent control at 31 and 61 DAT.

Treatment	Compounds	Active Ingredients	Rate per acre
1	Arsenal + RoundUp Pro	Imazapyr + glyphosate	2 pt + 1.5 qt
2	Arsenal	Imazapyr	2 pt
3	RoundUp Pro	Glyphosate	1.5 qt
4	Outrider	Sulfosulfuron	1.25 oz
5	Outrider	Sulfosulfuron	1.67 oz
6	Envoy	Clethodim	18 fl oz
7	Envoy	Clethodim	24 fl oz
8	Fusion	Fluazifop + fenoxyprop	7 fl oz
9	Fusion	Fluazifop + fenoxyprop	9 fl oz
10	Plateau	Imazapic	8 fl oz
11	Plateau	Imazapic	12 fl oz

Table 1: Treatment list for Miscanthus trial in Eastern Kentucky

<u>Results</u>

Treatments that included RoundUp Pro had statistically higher control rates than those that did not at all evaluation intervals (Table 2). The addition of RoundUp Pro to the Arsenal treatment dramatically increased control levels at 31 and 62 DAT and statistically increased control levels at 359 DAT. There was no significant increase in control levels with the Arsenal / RoundUp tank mix versus RoundUp alone.

Outrider failed to provide satisfactory control which is consistent with other warm season grass applications with this product. Outrider is labeled for cool season grass control, such as tall fescue, and had documented tolerance on warm season grasses, such as big bluestem. Envoy, a graminicide, provided higher control levels than Fusion, another type of graminicide, yet both products provided overall unsatisfactory control levels at the evaluation periods. Plateau provided extremely low levels of control in 2005. Outrider, Envoy, Fusion, and Plateau had no effect on Miscanthus 1 YAT.

Future work with Miscanthus will include the use of a MSO in combination with Arsenal to determine if MSO will increase herbicide efficacy. The study area used in 2005 will be retreated in 2006 to determine the effect of sequential applications of Round Up and Arsenal in increasing control levels from those reported here.

Identification and Control of Common Reed (*Phragmites australis* (CAV.) Trin. *ex* Steud.)

Introduction

Common reed, often referred to as phragmites, is a perennial invasive terrestrial grass that occurs across the United States. Although widely distributed across Europe, it is unclear as to the exact origin and method of introduction of this species. Categorized as a facultative wetland and obligate wetland species (USFWS 1996), phragmites can occur in a variety of moist to wet environments. The species can tolerate stagnate and flowing water, salt and alkaline conditions, and is commonly found in roadside ditches, marshes, and other wet area (Uva et al 1997). Individual stems can become very large (2 - 4 m in height) and form large monotypic stands. Stems are hollow, round, and become thicker towards the base of the plant. Leaves are fairly $\log (20 - 60 \text{ cm})$, flat, hairless, and have rough or sharp margins. Plants flower by mid summer in plume-like panicles with feathery spikelets that are purple at emergence and turn light brown with age. Plants rarely produce viable seed and reproduce mainly vegetatively through rhizomatous sprouting. This aids in its invasibility and spread as it is easily moved across sites through disturbances such as mowing, flooding, and road construction. Infestations of phragmites can be problematic in terms of degrading aquatic and terrestrial wildlife habitat and preventing roadside ditches and other waterway channels form operating efficiently.

Control options for phragmites are somewhat limited due to its usual proximity to aquatic environments. Miller (2004) recommends a 4 % glyphosate solution or a 1 % imazapyr solution applied as a foliar spray to control giant reed (*Arundo donax*), a species very similar to common reed. These herbicides are available for use for aquatic situations. These applications may cause unwanted damage to desirable grasses and forbs in the understory. This may be problematic since common reed can not readily establish itself in vegetated soil. Revegetation practices should be addressed when managing common reed infestations. Applying glyphosate or imazapyr through unconventional methods, such as 'wicking' or 'wiping' herbicide applicators may allow for effective control of common reed while allowing desirable vegetation to survive and compete against common reed regrowth. Kay et al (1999) realized effective control 1 YAT (1.2 live shoots / m² versus 29.3 live shoots / m² in the untreated) with imazapyr at 6 pt / ac when applied through a Weed Sweep, a type of cut – wipe herbicide applicator. Glyphosate, applied at 6 pt / ac, was ineffective in reducing live shoot counts 1 YAT (33.9 live shoots / m²).

A trial was installed in June of 2005 to examine the efficacy of glyphosate, formulated as Aquamaster®, and imazapyr, formulated as Habitat®, for their ability to control phragmites.

Methods and Materials

The study was located on the eastbound shoulder of the Western Kentucky Parkway in Hopkins County, KY between mile points 44 and 45. Five herbicide treatments and one untreated control were evaluated in a completely randomized block design with three replications (Table 1). Treatments were applied on June 16th, 2005 using a Teejet XP BoomJet® boomless tip. Plots were 12' X 25' and treated at 20 GPA. Percent control was visually estimated at 53 and 79 DAT. Since the plots were along the shoulder and in the mowing zone the treated areas were mowed approximately 2 - 3 WAT and again at approximately 8 WAT.

Results

The low rate of glyphosate tested (4 pt / ac) resulted in significantly lower control levels compared to the low rate of imazapyr tested (4 pt / ac) at 53 DAT. Imazapyr at 4 pt / ac provided the highest level of control (85 %) at 53 DAT (Table 1). There were no significant differences between treatments in control levels as the trial progressed through 79 DAT as all treatments had control levels between 73 % and 78 %.

The effect of the mowing on the ability of the herbicide to completely translocate though the plant and control regrowth is not yet known. The mowing of the plots also may have affected the variance in the data collected during the same growing season. The study will be reinstalled in the summer of 2006.

There was a visual effect present in the difference in the glyphosate and imazapyr treatments and the amount of damage to the understory. Tall fescue was severely damage in plots containing glyphosate while minimal damage was observed in the imazapyr alone treatments. This should be considered when making management recommendations.

Evaluation of Imazapyr, Glyphosate, and Triclopyr for Japanese Knotweed (*Polygonum cuspidatum* Sieb. & Zucc.) Control

Introduction

Japanese knotweed is a federally listed invasive perennial native to Asia (National Agricultural Library 2004). This herbaceous plant (sometime referred to as semi woody) was introduced into England in the early 1800s and was subsequently introduced into North America as an ornamental (Figueroa 1989, Uva et al 1997). This species has now spread across the Pacific Northwest, Midwest, and eastern United States (USDA NRCS 2004).

Japanese knotweed is problematic for land managers due to its aggressive nature and reproduction capabilities. The plant can establish itself on a wide array of site conditions but can establish and grow exceedingly well in areas of partial to high sunlight and moist well-drained soils such as roadsides, utility rights-of-way, and river and stream banks (McCormick 2000, Uva et al 1997). Stems are hollow and jointed, much like bamboo, and can reach heights up to 2 meters (approximately 10 feet). Plants form either male and female white flowers (dioecious) in late summer and form three sided seed like fruit. There is some confusion as whether or not seeds produced from plants naturalized in the United States are viable. Pure strains of Japanese, giant, or Himalayan knotweed are thought not to produce viable seed while hybrid varieties can produce viable seeds (Soll 2004). Japanese knotweed can also reproduce vegetatively from thick rhizomes that can reach 40 to 60 feet in length and annual growth of 8 feet is not uncommon (McCormick 2000). This vegetative reproduction can lead to the formation of dense colonies of Japanese knotweed that can out compete native species. Above ground portions usually die with a hard frost while the below ground rhizomes remain viable for growth the following year.

Individual plant parts created from mechanical mowing can remain viable and lead to the spread of this plant. Due to its habitat usually occurring near flowing water, flooding disturbances can transport plant parts to be deposited in uncolonized areas further compounding the problem. Homeowner mowing clippings and vehicle transport of plant parts have also lead to the spread of Japanese knotweed (Figueroa 1989).

Methods and Materials

A study was initiated in June of 2005 to evaluate herbicides labeled for use near and around aquatic areas. Treatments included glyphosate (formulated as Aquamaster®), imazapyr (formulated as Habitat®), and triclopyr (formulated as Garlon 3A®). The study was located along Bonnyman Road in Perry County, KY. Five treatments were installed in a completely randomized block design with three replications and applied at 50 GPA using a boomless tip mounted on a CO_2 sprayer on an ATV. All treatments included NIS at 0.25 % v/v. Plots were evaluated for percent control (estimated by burndown) at 21 and 58 DAT.

Results and Discussion

The combination of Aquamaster and Garlon 3A provided significantly higher control levels (88%) at 21 DAT than all other treatments (Table 1). Aquamaster at 5 qt / ac provided the next highest level of control (57%) at the same evaluation interval. Habitat at 3 pt / ac was not effective (12%) at 21 DAT. The Aquamaster / Garlon 3A tank mix resulted in high control levels (95%) at 58 DAT and was statistically higher than all other treatments. There were no statistical differences among the remaining treatments at 58 DAT and these treatments did not exceed 42% control.

The Habitat at 3 pt / ac treatment provided the highest level of control (95 %) 1 growing season after treatment (1 GSAT) (Table 1). The Habitat alone treatment also resulted in the lowest amount of variance in control levels 1 GSAT (Figure 1). This indicates the consistent level of control provided by Habitat at 3 pt / ac in this trial. Aquamaster alone and Aquamaster + Habitat provided the next highest levels of control (82 % and 77 % respectively) at the same evaluation interval. There were no significant differences between these three treatments 1 GSAT. Treatments using Renovate 3 resulted in extremely poor control levels 1 GSAT. This indicates triclopyr's ability to provide quick burndown of Japanese knotweed in the same growing season of application but its inability to provide long term control.

Identification and Control of Serecia Lespedeza (*Lespedeza cuneata* (Dum. – Cours.))

Introduction

Serecia lespedeza, otherwise known as Chinese lespedeza, is a perennial leguminous forb native to Asia. Introduced in the late 1800s as a potential forage species, it was later used as a reclamation species planted on acidic and low fertility soils (Koger 2003). Government programs also supported the use of serecia lespedeza as a soil stabilizer and food source for wildlife plantings (mainly quail). Infestations occur across the southeastern United States from Oklahoma and Texas to Virginia, the Carolinas, to Florida.

Serecia lespedeza is an upright forb and can reach heights up to 6 feet (Miller 2004). Stems are angular, herbaceous to semi woody, and are grey-green in color with pubescence. Leaves are trifoliate, alternate in arrangement, and appear in clusters. Flowers appear from July to September in the upper leaf axils and are white in color with purple markings. Seeds occur in round single seeded legume pods October through March. Typical seed yields range from 205 to 1015 lbs / ac (Farris et al 2004) and these seeds can remain viable for decades (Miller 2004). Along with this prolific seed production, serecia lespedeza has the ability to reproduce vegetatively from crown bud regrowth after disturbance, further aiding in its invasibility. Serecia lespedeza can occur in wide array of sites including roadsides, forest openings, dry upland sites, and moist savannahs. Serecia lespedeza is flood tolerant and somewhat intolerant to shade.

Recommendations for control include herbicide applications of triclopyr, metsulfuron methyl, and clopyralid. Prescribed burning and mowing amy increase herbicide efficacy. Miller (2004) recommends foliar sprays of triclopyr ester as a 2 % solution, metsulfuron methyl at 0.75 oz per acre, clopyralid as a 0.2 % solution, hexazinone as a 2 % solution, or glyphosate as a 2 % solution. Cargill et al (2002) found effective control 2 months after treatment (MAT) with 1 and 1.5 pts of Garlon 4 per acre (92 and 98 % control respectively). Fluroxypyr (Vista®) realized 94 % and 98 % control when tested at 1 and 1.3 pts per acre at the same evaluation interval. These levels of control where maintained at 3 MAT.

Overdrive® is a granular herbicide labeled for use in noncrop and rights-of-way areas. It is a combination of dicamba (0.5 lb ae / lb of product and diflufenzopyr (0.2 lb ae / lb of product). A study was initiated in the summer of 2005 to examine Overdrive in combination with Vista for serecia lespedeza control. Specifically, treatments were designed to test the ability of Overdrive to control serecia lespedeza in combination of low rates of Vista.

Methods and Materials

The study was located on a reclaimed coal mine on the property of Hopkins County Coal in Hopkins County, KY. Serecia lespedeza was the dominant species with approximately 95 % cover in the study area. Height of lespedeza ranged from 1.5' to 4' at application. The trial was installed as a randomized complete block design with three replications and 13 treatments (including an untreated control) (Table 1). Plots were 10' by 20' with a majority of the cover (> 90%) in each plot being serecia lespedeza. Treatments included Vista at 24, 16, 12, and 8 fl oz / ac alone and in combination of either 4 or 6 oz of Overdrive per acre. Applications were made at 20 GPA using a CO_2 powered boom sprayer mounted on an ATV and all treatments included methylated seed oil (MSO) at 32 fl oz / ac. Treatments were applied on June 16, 2005 and rated at 19, 35, 53, and 89 DAT for percent control.

Results

There were no significant differences between any treatment at the first evaluation interval (19 DAT) and control levels ranged from 37 % (treatment 4) and 50 % (treatment 5) at this evaluation interval (Table 1). The highest control levels realized at the 35 DAT interval were seen with the treatments incorporating the high rate of Vista (24 fl oz) and Vista alone at 16 fl oz. This trend continued through all following evaluation dates and is shown visually in Figure 1. The highest level of control at 53 DAT came from the high rate of Vista (24 fl oz) tank mixed with the high rate of Overdrive (6 oz) although this treatment was not significantly different than any other treatment except for Vista @ 12 fl oz + Overdrive @ 6 oz. The Vista alone at 16 fl oz provide high control levels (91 %) at 89 DAT; however' was only significantly higher than the Vista @ 12 fl oz + Overdrive (a) 6 oz and the Vista (a) 8 fl oz + Overdrive 6 oz treatments. There was no significant difference between this treatment and either the Vista alone at 8 fl oz or the Vista at 8 fl oz + Overdrive at 4 oz at 89 DAT. This indicates the potential of Overdrive to increase the efficacy of Vista at low rates in controlling serecia lespedeza; however, the difference in control levels between the high and low rates of Vista both with and without Overdrive may be operationally unacceptable.

The study site was dominated by a dense serecia lespedeza infestation and represents a 'worse case scenario'. The treatments examined here may be more efficacious controlling less dense populations.

Dormant Stem Herbicide Applications for Bush Honeysuckle Control

Introduction

Bush honeysuckle is an inclusive term used to describe several species of an invasive woody shrub. These species include Amur honeysuckle (*Lonicera maackii* (Rupr.) Herder), Morrow's honeysuckle (*Lonicera morrowii* Gray), and Tatarian honeysuckle (*Lonicera tatarica* L.). These three species were introduced from Eurasia in the 17 and 1800s and planted as ornamentals. Their spread to rural and forested areas is due to their planting as wildlife food sources and seed dispersal by animals (mostly birds). These deciduous woody shrubs are multi-stemmed, shade tolerant, prolific seed producers, and have the ability to sprout from rootstocks after disturbance. These characteristics aid in its invasibility and ability to dominate a site and create monocultures.

Traditional herbicide screening literature on these species is minimal. Hartman and McCarthy (2004) reported 98% and 94% mortality one year after treatment by utilizing individual stem injections of glyphosate with an EZ-ject and a cut stump treatment of 50% solution of glyphosate, respectively. Literature from conservancy and invasive plant groups commonly recommends foliar sprays of a 1 to 2 % solution of glyphosate and cut stump treatments of a 20 % glyphosate solution. Miller (2004) recommends a 2 % solution of glyphosate as a foliar spray, a 20 % solution of triclopyr ester mixed with basal oil as a individual stem basal treatment, and either a 20 % glyphosate solution or a 10 % imazapyr solution as a cut stump treatment as control options.

Dormant stem herbicide applications may provide operationally effective control of bush honeysuckle while providing several benefits. These treatments may be performed during the winter months allowing crews to remain productive. Unlike individual stem basal treatments, dormant stem applications may be a broadcast treatment and therefore increase the productivity of crews (i.e. acres or plants treated). Public visibility and complaints may be reduced as the effect of brownout would be reduced. Off target damage to desirable species (either woody or herbaceous) may be reduced if the application is performed during the dormant season of these desirables and if selective chemistry is used. These types of herbicide treatments can be cost prohibitive; however, so it would be beneficial to know if plant size (i.e. height or number of stems per rootstock) affected herbicide efficacy to allow for site specific applications. A study was initiated in March 2005 to investigate the ability of broadcast herbicide treatments to dormant stems to provide effective control of Amur honeysuckle. Specifically, the study evaluated 1) the ability of several herbicide treatments to control bush honeysuckle and 2) determine if any relationship existed between either height of target plant or number of stems from a rootstock of a target plant and control levels from dormant stem herbicide treatments.

Methods and Materials

Five treatments were evaluated in a completely randomized design with three replications located in Lexington, KY. Treatments included BK800 (a.i. 2,4 - D, 2,4 - DP ester and dicamba acid) at 3 % v/v plus crop oil concentrate (COC) at 2.5 % v/v, Garlon 4 (a.i. triclopyr ester) at 1.5 % v/v plus COC at 2.5 % v/v, BK 800 at 1 % v/v plus Garlon 4 at 1.5 % v/v plus COC at 2.5 % v/v, BK800 at 3 % v/v plus Garlon 4 at 1.5 % v/v, and COC alone at 2.5 % v/v. Each plot included ten bush honeysuckle rootstocks, which were labeled and numbered, and estimated height and number of stems per rootstock were recorded before application. Treatments were applied in early March 2005 while plants were still dormant using a hand gun and entire stems were treated to the point of runoff. Plots were evaluated for percent control (estimated by amount of leafout) at 60 and 120 DAT. Treatment means were compared using Fishers LSD at p = 0.05. Simple linear regressions were performed in SAS® by each treatment using height and number of stems as individual regressors to predict control levels at p = 0.05 for significant models.

Results

The BK 800 at 3 % v/v plus Garlon 4 at 1.5 % v/v treatment provided significantly higher control levels (85 %) than BK 800 alone (71 %) at 60 DAT. There were no significant difference between the BK 800 and Garlon 4 tank mixes (79 % for BK 800 at 1 % tank mix) and the Garlon 4 alone treatment (78 %) at 60 DAT. The BK800 alone treatment was significantly lower (71 %) than all other treatments at 60 DAT. There was no observable effect at 60 DAT of treating stems with a COC / water mix. There were no significant differences between the BK 800 at 3 % plus Garlon 4 at 1.5 % (89 %), Garlon 4 at 1.5 % (83 %), BK 800 at 1 % plus Garlon 4 at 1.5 % (83 %), and BK 800 at 3 % (81 %) at 120 DAT. Treating bush honeysuckle with COC at 2.5 % resulted in 14 % control at 120 DAT.

Only two significant models could be produced to predict control levels at 120 DAT of the 10 models tested (2 variables X 5 treatments). The BK 800 at 3 % plus Garlon 4 at 1.5 % treatment could be predicted using stem height at 120 DAT (y = 107.23x - 2.52, p = 0.0233, $R^2 = 0.1705$) (Figure 1). Even though the model was significant it is of little operational use due to its low coefficient of determination (R^2). The second model produced used the number of stems to predict the effect of COC at 2.5 % 60 DAT. This is of little operational value as well since there were low control levels using COC alone at 120 DAT. The lack of significant models may be the result of variability present in the control data; however, it is more likely that there is no significant relationship between the two physiological variables measured, the herbicides used, the application technique screened here and the level of control produced for any treatment tested.

Evaluation of this trial 1 year after treatment (YAT) resulted in no statistically significant difference between any of the herbicide treatments (Table 1). The only difference between treatments 1 YAT occurred between the COC alone treatment, which resulted in no control 1 YAT, and all other treatments. Control levels of all herbicide treatments are deemed ineffective. Models tested for prediction of response yielded no

effective results using either height or number of stems for any herbicide treatment one year after application.
